QTL Studies- Past, Present and Future

David Evans

University of BRISTOL

Genetic studies of complex diseases have not met anticipated success

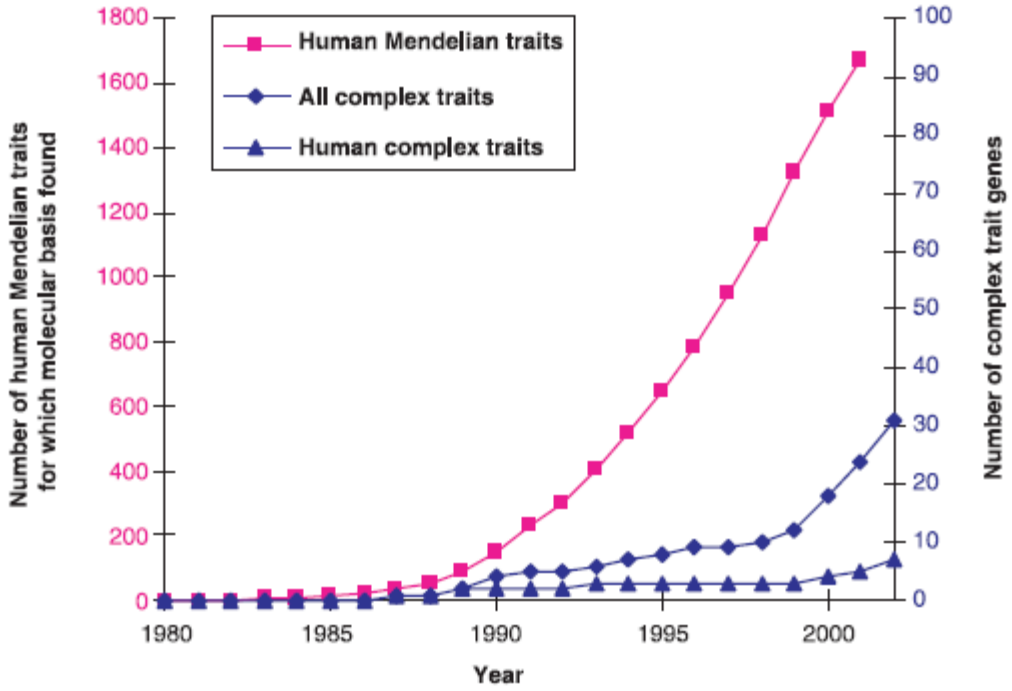

Fig. 1. Identification of genes underlying human Mendelian traits and genetically complex traits in humans and other species. Cumulative data for human Mendelian trait genes (to 2001) include all major genes causing a Mendelian disorder in which causal variants have been identified (*58*, *59*). This reflects mutations in a total of 1336 genes. Complex trait genes were identified by the whole-genome screen approach and denote cumulative year-on-year data described in this review.

Glazier et al, Science (2002) 298:2345-2349

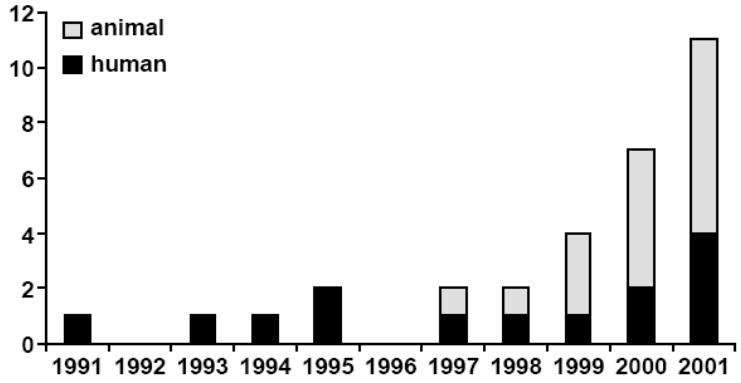

Fig. 1 Number of genes identified from QTL by year. Genes for human QTL are shown in black and genes for experimental models (mouse, rat, and pig) in white. The first QTL gene was identified in 1991. There are 14 from humans and 17 from animal models (5 from rats, 11 from mice, 1 from pigs). These add up to more than 29 because some were identified in both humans and rodent models.

Multiple Rare Variant Hypothesis?

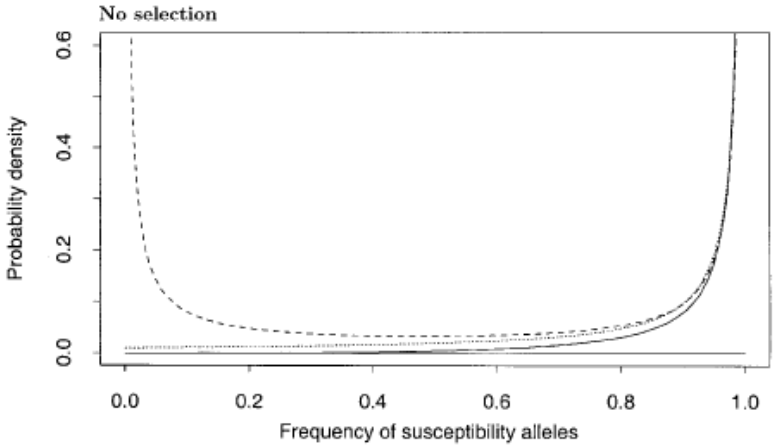
- GWA assumes that common variants underlie common diseases

Are Rare Variants Responsible for Susceptibility to Complex Diseases?

Jonathan K. Pritchard

Department of Statistics, University of Oxford, Oxford

Little is known about the nature of genetic variation underlying complex diseases in humans. One popular view proposes that mapping efforts should focus on identification of susceptibility mutations that are relatively old and at high frequency. It is generally assumed—at least for modeling purposes—that selection against complex disease mutations is so weak that it can be ignored. In this article, I propose an explicit model for the evolution of complex disease loci, incorporating mutation, random genetic drift, and the possibility of purifying selection against susceptibility mutations. I show that, for the most plausible range of mutation rates, neutral susceptibility alleles are unlikely to be at intermediate frequencies and contribute little to the overall genetic variance for the disease. Instead, it seems likely that the bulk of genetic variance underlying diseases is due to loci where susceptibility mutations are mildly deleterious and where there is a high overall mutation rate to the susceptible class. At such loci, the total frequency of susceptibility mutations may be quite high, but there is likely to be extensive allelic heterogeneity at many of these loci. I discuss some practical implications of these results for gene mapping efforts.



How many diseases does it take to map a gene with SNPs?

Kenneth M. Weiss[1] & Joseph D. Terwilliger[2]

"They all talked at once, their voices insistent and contradictory and impatient, making of unreality a possibility, then a probability, then an incontrovertible fact, as people will when their desires become words."
—W. Faulkner, *The Sound and the Fury*, 1929

"I found one! I found one!"

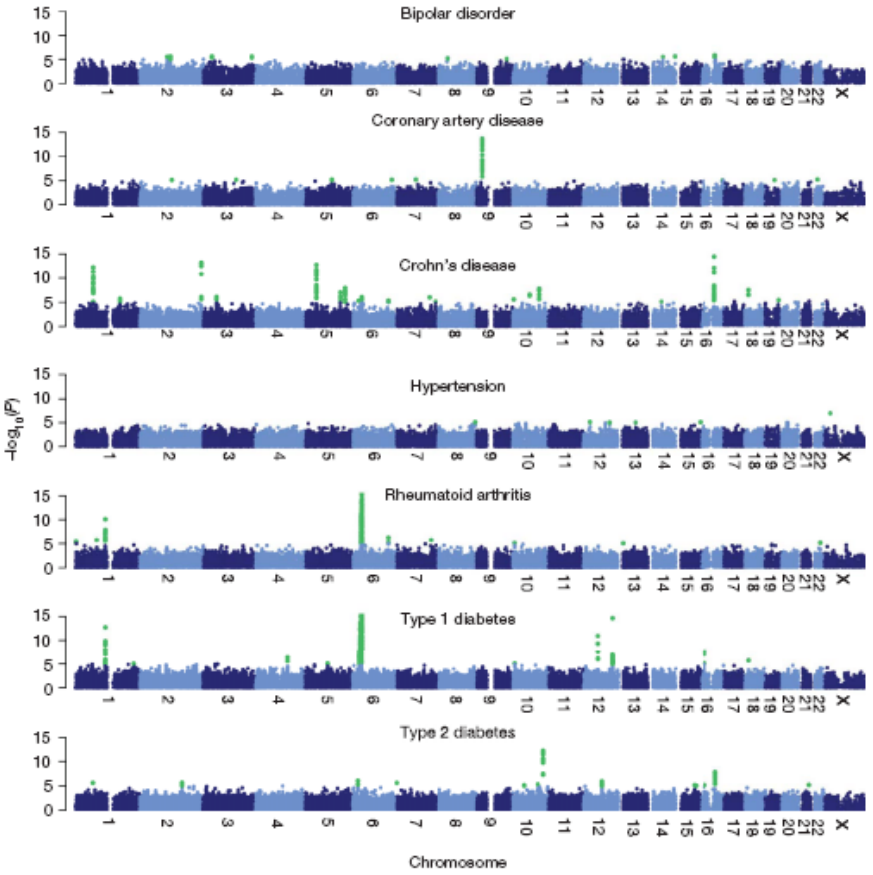
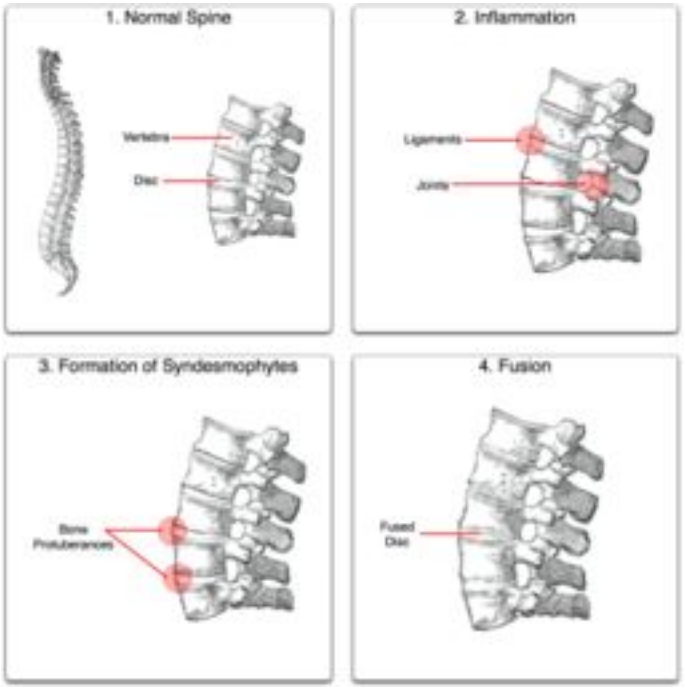
Genome-wide association study of 14,000 cases of seven common diseases and 3,000 shared controls

The Wellcome Trust Case Control Consortium*

There is increasing evidence that genome-wide association (GWA) studies represent a powerful approach to the identification of genes involved in common human diseases. We describe a joint GWA study (using the Affymetrix GeneChip 500K Mapping Array Set) undertaken in the British population, which has examined ~2,000 individuals for each of 7 major diseases and a shared set of ~3,000 controls. Case-control comparisons identified 24 independent association signals at $P < 5 \times 10^{-7}$: 1 in bipolar disorder, 1 in coronary artery disease, 9 in Crohn's disease, 3 in rheumatoid arthritis, 7 in type 1 diabetes and 3 in type 2 diabetes. On the basis of prior findings and replication studies thus-far completed, almost all of these signals reflect genuine susceptibility effects. We observed association at many previously identified loci, and found compelling evidence that some loci confer risk for more than one of the diseases studied. Across all diseases, we identified a large number of further signals (including 58 loci with single-point P values between 10^{-5} and 5×10^{-7}) likely to yield additional susceptibility loci. The importance of appropriately large samples was confirmed by the modest effect sizes observed at most loci identified. This study thus represents a thorough validation of the GWA approach. It has also demonstrated that careful use of a shared control group represents a safe and effective approach to GWA analyses of multiple disease phenotypes; has generated a genome-wide genotype database for future studies of common diseases in the British population; and shown that, provided individuals with non-European ancestry are excluded, the extent of population stratification in the British population is generally modest. Our findings offer new avenues for exploring the pathophysiology of these important disorders. We anticipate that our data, results and software, which will be widely available to other investigators, will provide a powerful resource for human genetics research.



Ankylosing Spondylitis



- Auto-immune arthritis resulting in fusion of vertebrae
- Prevalence of 0.4% in Caucasians. More common in men.
- Often associated with psoriasis, IBD and uveitis

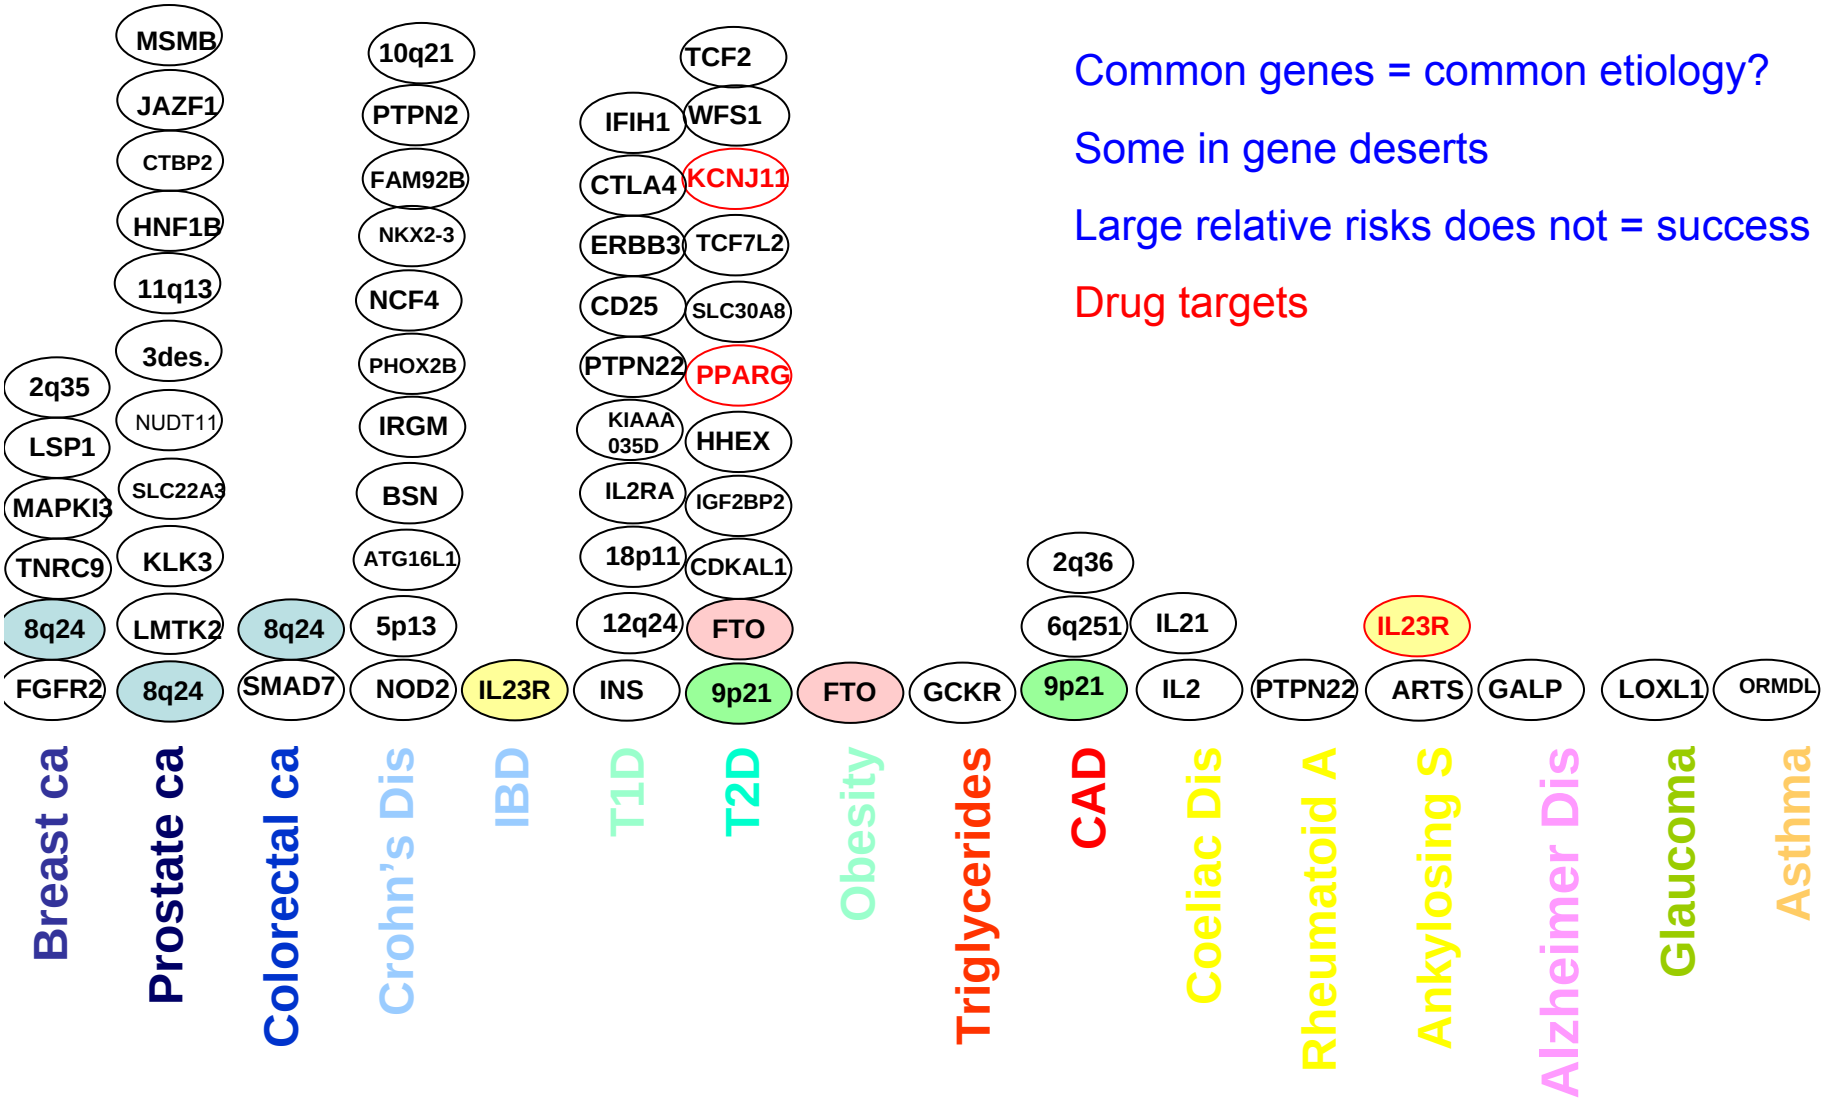
Successes…



Common genes = common etiology?

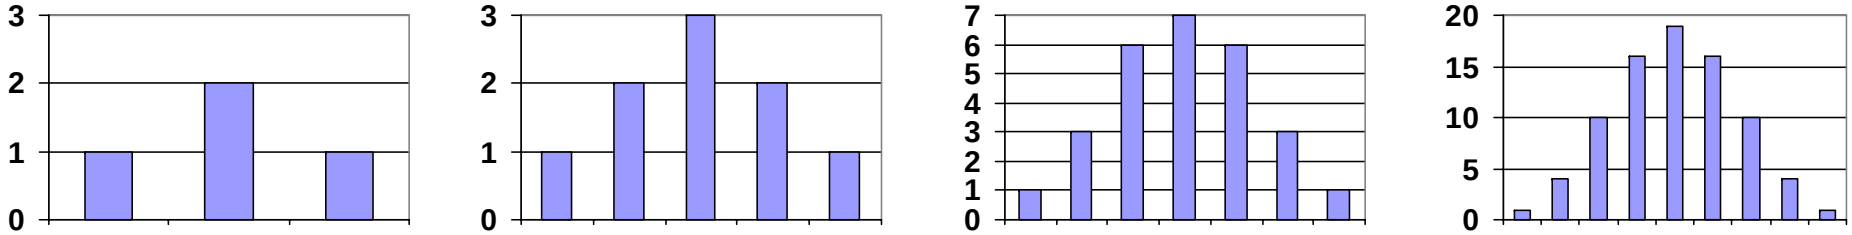
Some in gene deserts

Large relative risks does not = success

Drug targets

What About Quantitative Traits?

1 Gene	2 Genes	3 Genes	4 Genes
→ 3 Genotypes	→ 9 Genotypes	→ 27 Genotypes	→ 81 Genotypes
→ 3 Phenotypes	→ 5 Phenotypes	→ 7 Phenotypes	→ 9 Phenotypes



Central Limit Theorem → Normal Distribution

- Quantitative genetics theory suggests that quantitative traits are the result of many variants of small effect
- Unselected samples
- The corollary is that very large sample sizes will be needed to detect these variants in UNSELECTED samples

Does my bum look big in these genes?

By LYNDSAY MOSS
HEALTH CORRESPONDENT

OBESITY can now legitimately be blamed on your genes, scientists said yesterday.

Variations in a gene carried by 16 per cent of the population can make people up to 70 per cent more likely to become obese, according to a major study involving thousands of Scottish volunteers.

A genetic variation identified by scientists can make people 70 per cent more likely to be obese. Picture: AFP/Getty Images

The researchers said they had now identified the clearest genetic link yet to weight gain and obesity in the population.

The findings could eventually lead to new treatments for obesity, which affects more than a fifth of adults in the UK.

The research, funded by the Wellcome Trust, studied the genome - all the genetic material in a living object - in 2,000 people with type-2 diabetes and a 3,000-strong control group.

What's Going On?

- Loci identified by GWAs don't have linkage peaks over them

  Linkage analysis lacks power?

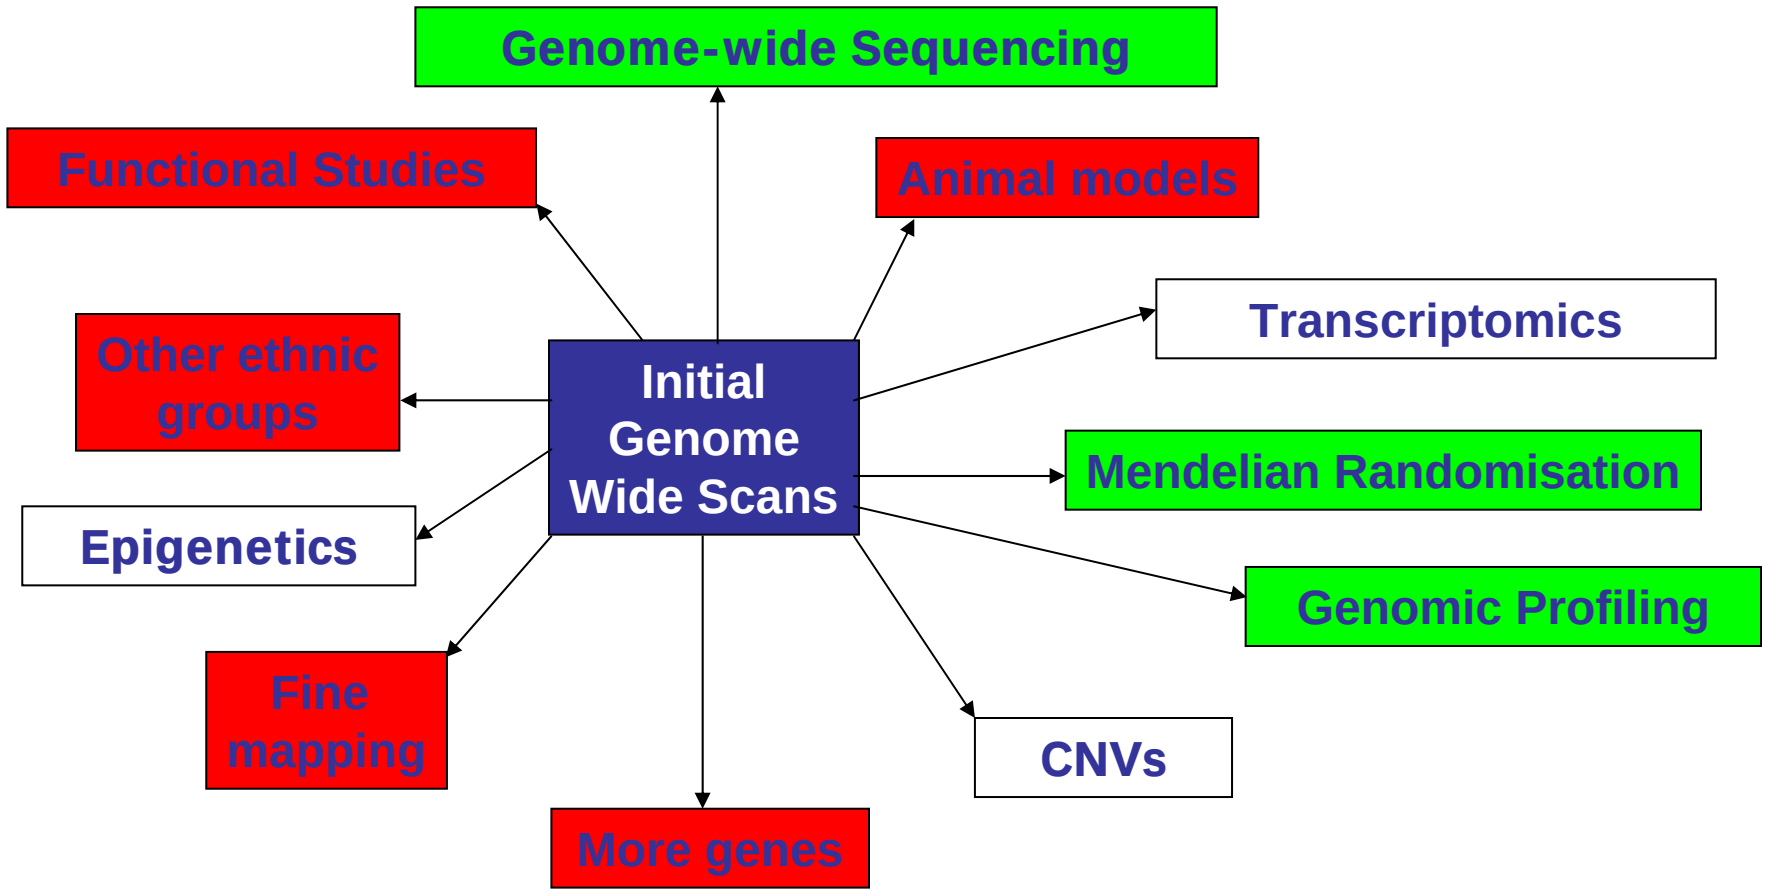
- Areas identified by linkage don't have significant assocation hits over them

  Type I error?

  Power?

- BUT…what if linkage analysis and association analysis identify different types of loci?

What next?



Genome-wide Sequencing
Functional Studies
Animal models
Transcriptomics
Other ethnic groups
Initial Genome Wide Scans
Mendelian Randomisation

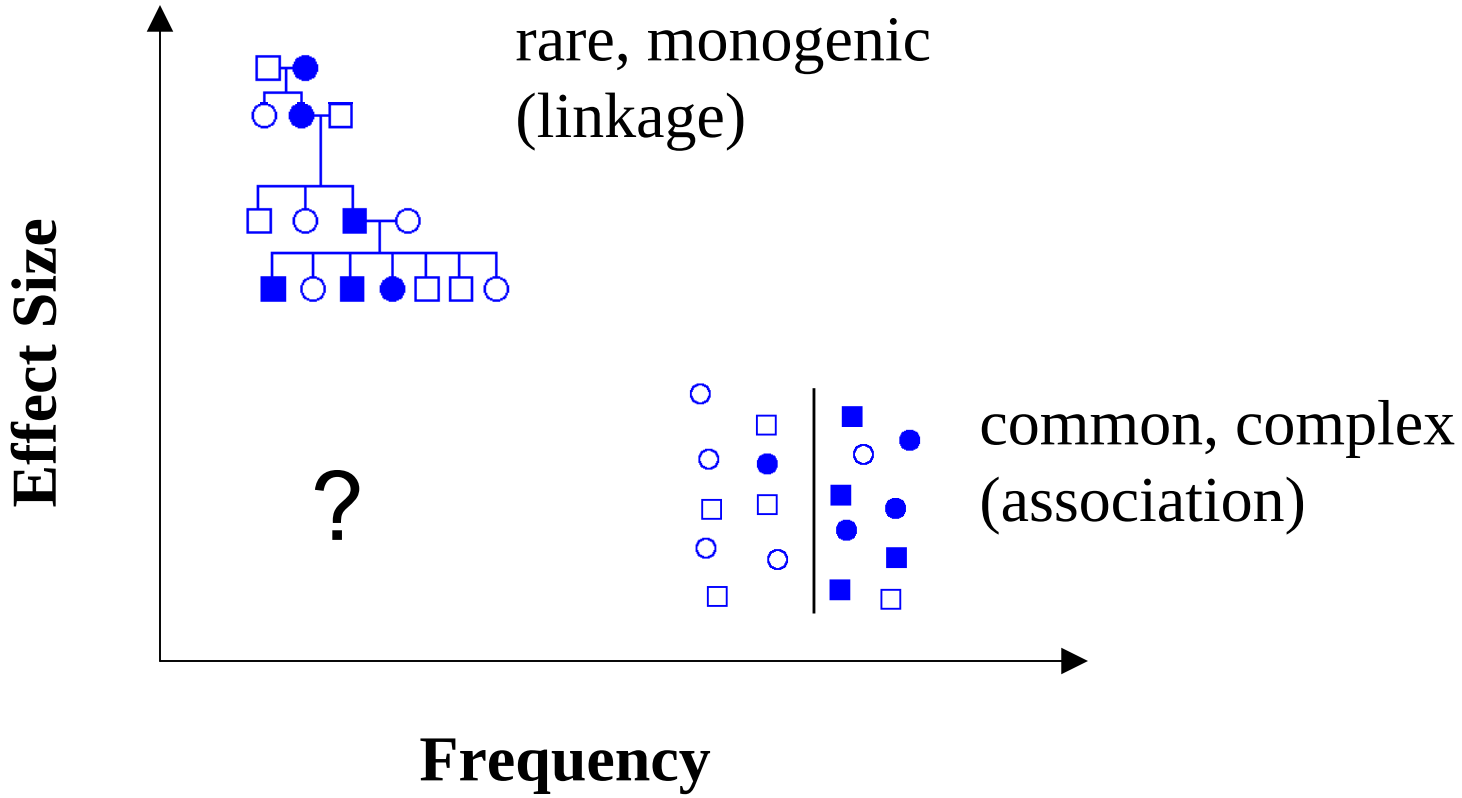
"Low hanging fruit"

"Rotten Fruit"

Methods of gene hunting



Genome-wide Sequencing

- Sequence individuals' genomes
- Will identify rare variants
- But will we have enough power?

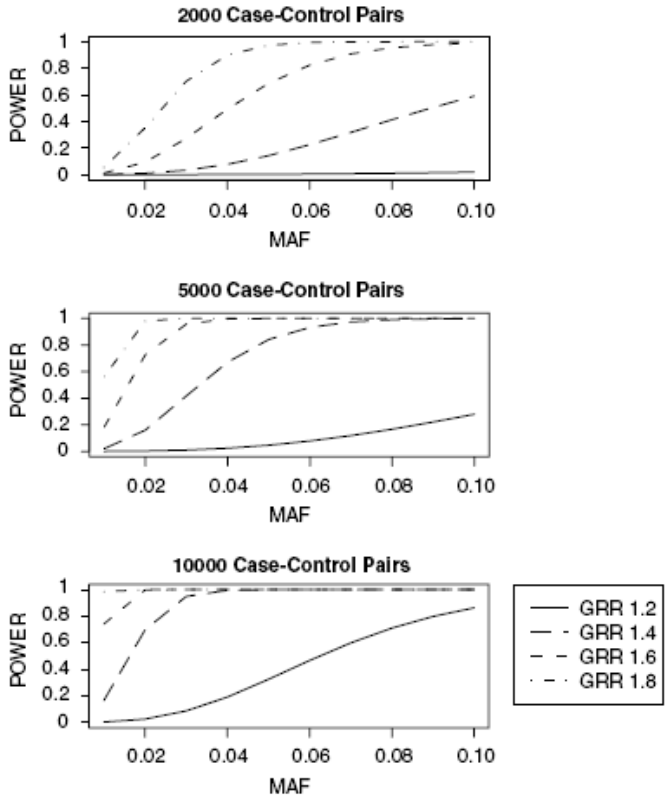


Figure 2 Relationship between MAF, heterozygote GRR, and power to detect association assuming a multiplicative disease model. Results are shown for 2000, 5000, and 10 000 case–control pairs assuming a disease prevalence of 1% and a type I error rate of $\alpha = 3.6 \times 10^{-6}$. The figure illustrates that it is possible to detect rare variants of intermediate penetrance using current sample sizes of 2000 case–control pairs. To detect rare alleles of smaller effect, far larger sample sizes will need to be employed.

Evans et al. (2008) *EJHG*

Genomic Profiling

- The idea of using genetic information to inform diagnosis
- Predictive testing in the case of monogenic diseases has been used for years (1300+ tests available) (e.g. Phenylketonuria)
- Not possible in complex diseases as effects of an individual variant is so small
- BUT…if we consider several predisposing genetic and environmental factors, can we predict disease?

Genomic Profiling

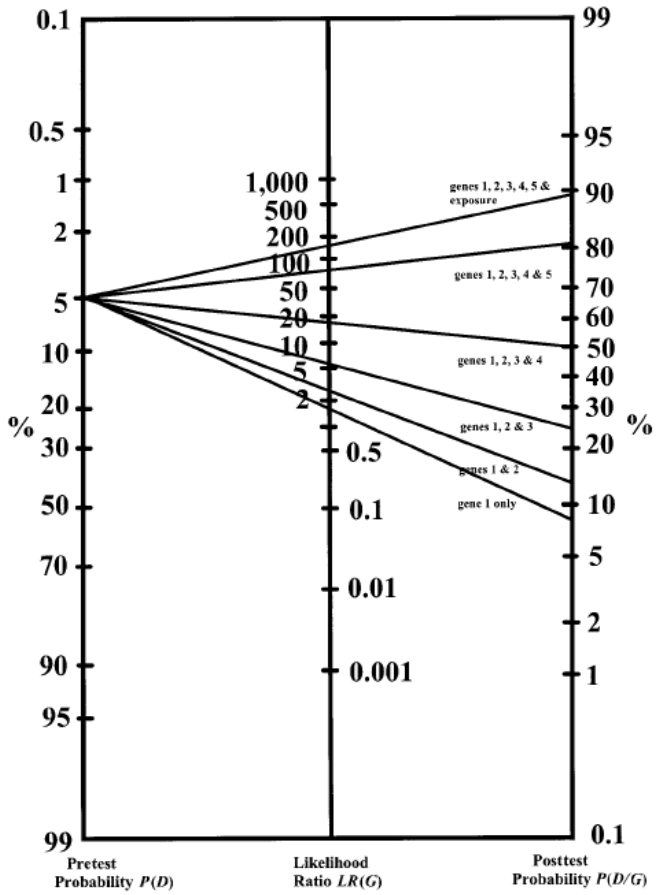

Figure 1 Power of a panel of genetic tests and exposure on predictability of the common disease (simulated data)

(from Yang et al. 2003 AJHG)

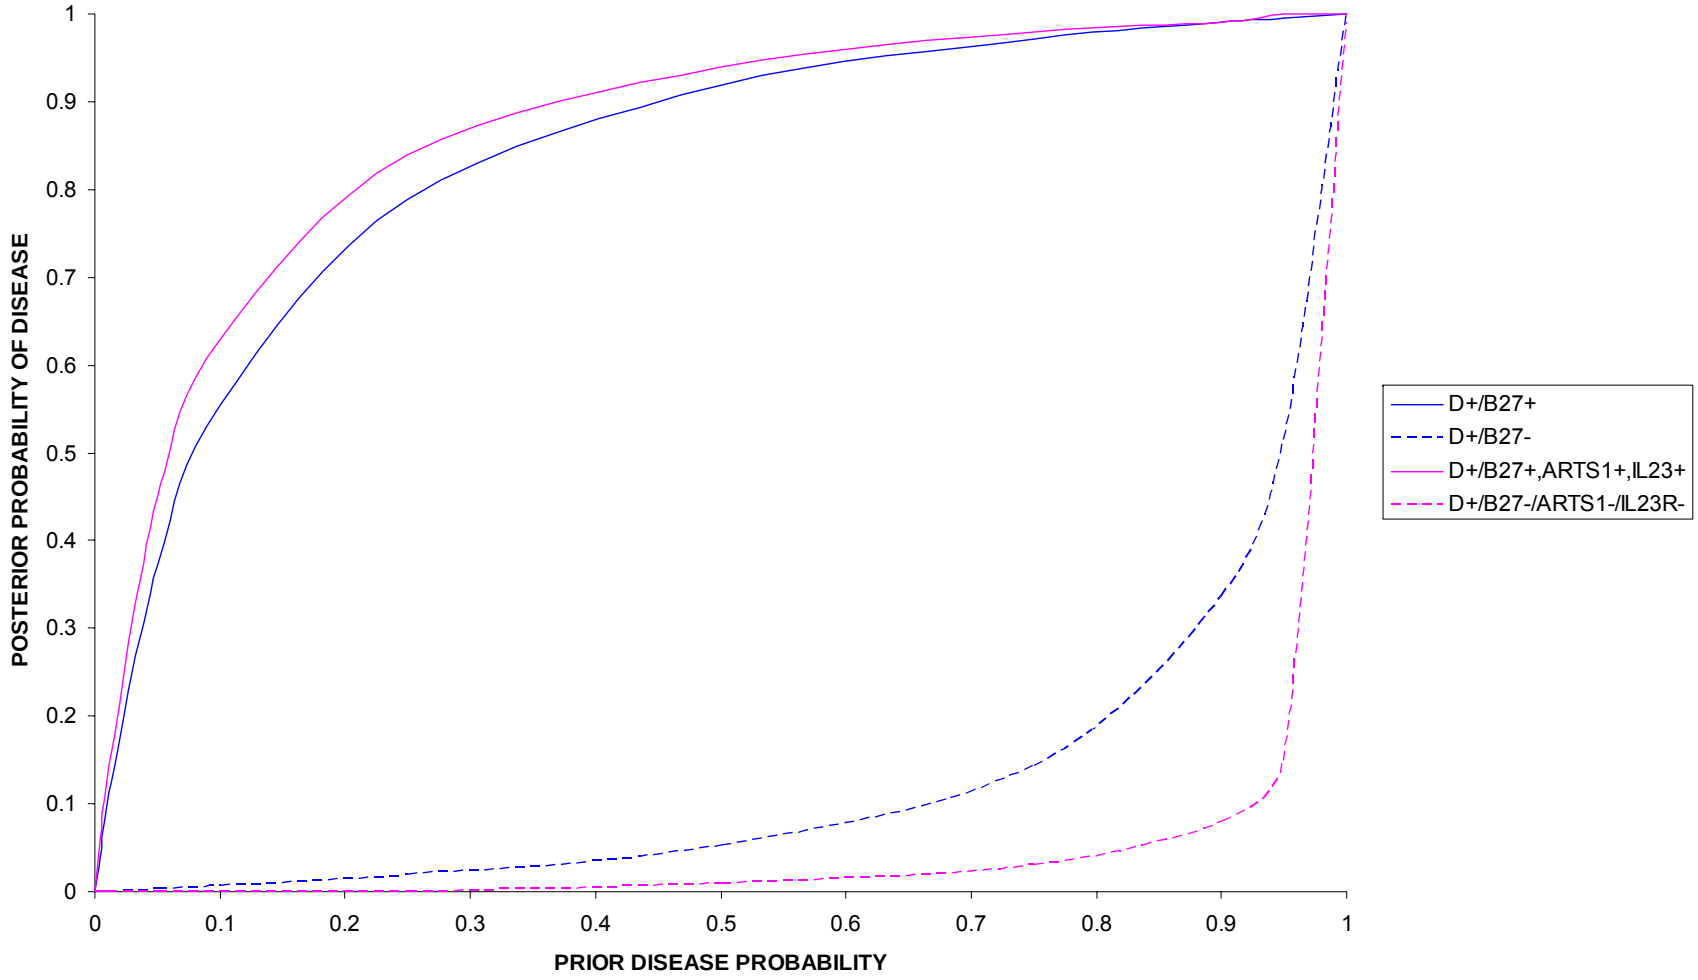
=> Give up and go home?

Ankylosing Spondylitis



(Brown & Evans, in prep)

- Prevalence of B27+, ARTS1+,IL23R+ is 2.4%
- Prevalence of B27-, ARTS1-, IL23R- is 19%

Using Genetics to Inform Classical Epidemiology

Observational Studies

- Fanciful claims often made from observational studies
- In a case-control study, a group of diseased individuals are recruited (Cases); A group of individuals without disease are gathered (Controls); Both groups are then measured retrospectively on an exposure of interest; A test of association is performed
- Example: Obesity (Exposure) and Coronary Heart Disease (Outcome)

	Obesity	
	Yes	No
CHD	200	100
Control	50	250

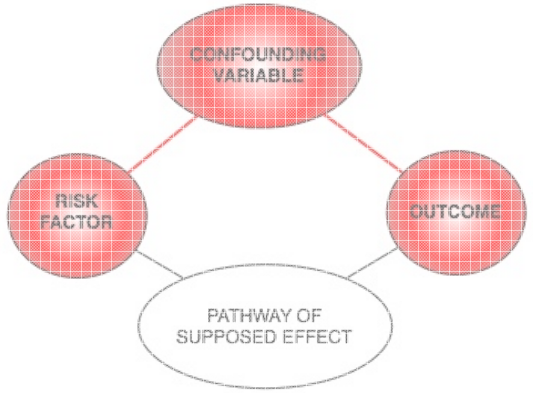
Odds of obesity in cases: 200/100 = 2

Odds of obesity in controls: 50/250 = 0.2

Odds Ratio: 2/0.2 = 10

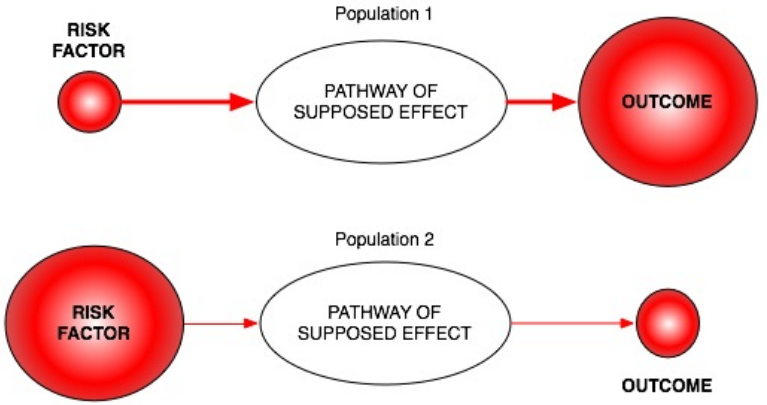
Classic limitations to "observational" science

- Confounding

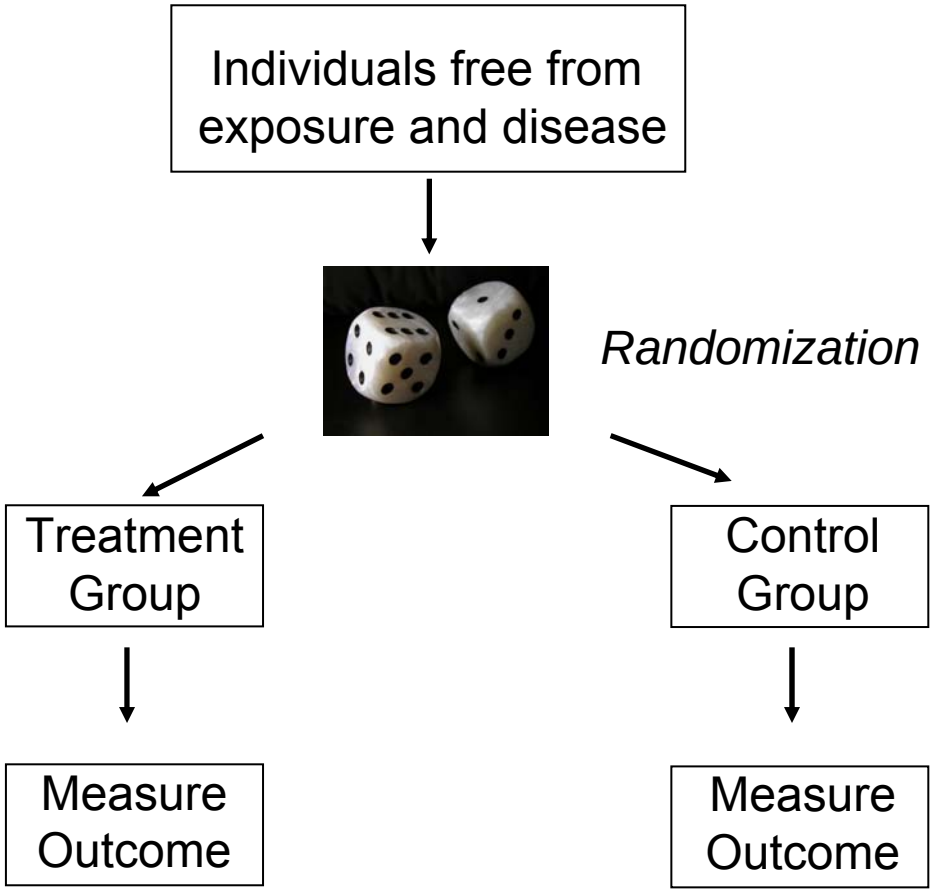


- Reverse Causation

- Bias



Randomized Control Trials

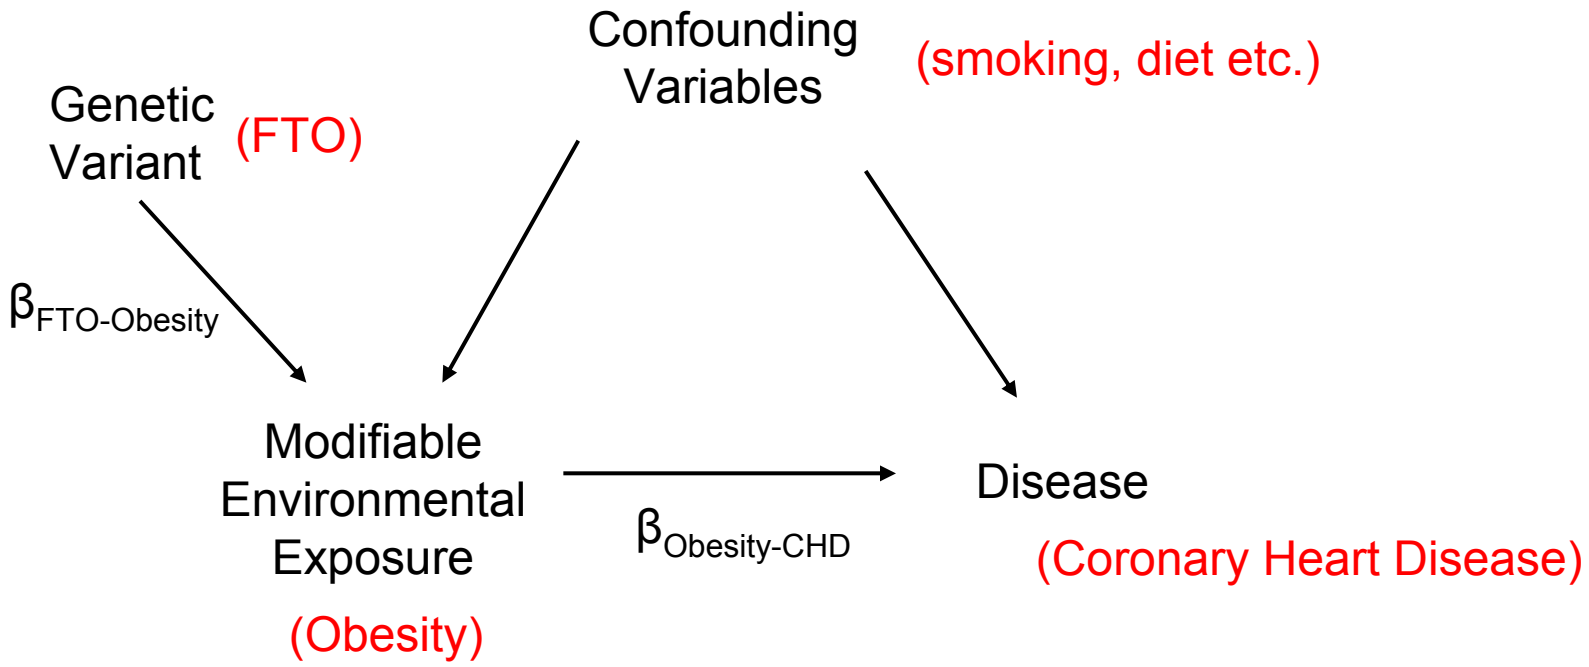


- Randomization controls for confounding
- Reverse causation impossible
- Gold standard for assessing causality

Mendelian Randomization

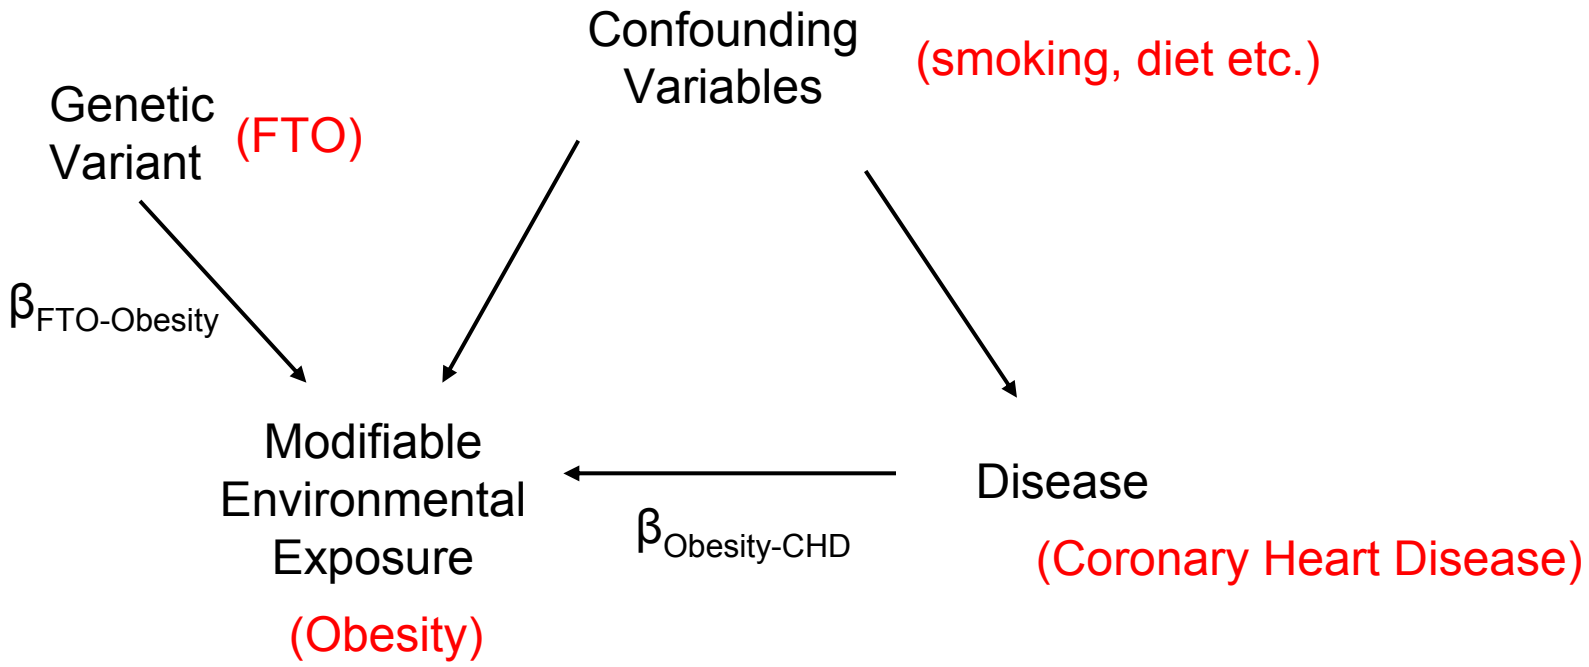
- RCTs not always ethical or possible
- Fortunately nature has provided us with a natural randomized control trial !
- Mendel's law of independent assortment states that inheritance of a trait is independent (randomized) with respect to other traits
- Therefore individuals are randomly assigned to three groups based on their genotype (AA, Aa, aa) independent of outcome
- Assessing the relationship between genotype, environmental risk factor and disease informs us on causality

Mendelian Randomization



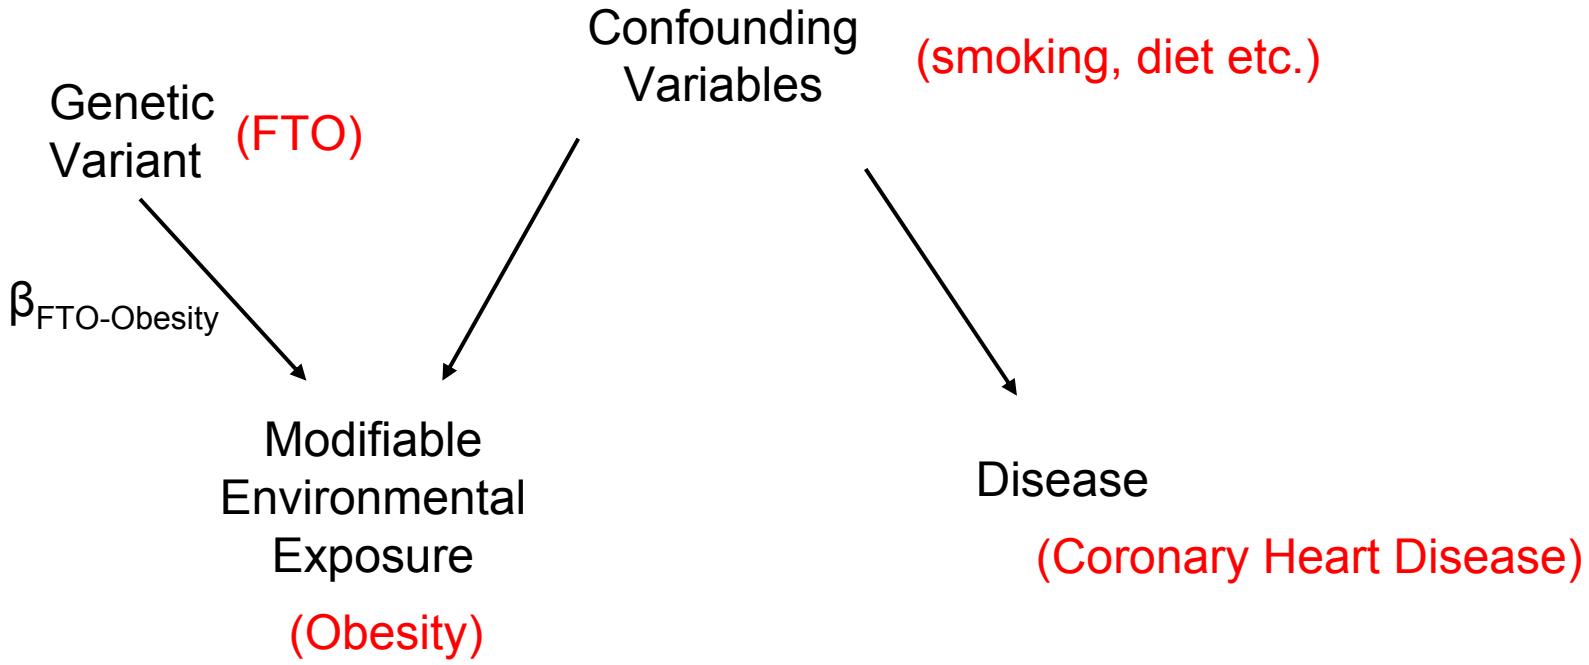
- If obesity causes CHD then the relationship between FTO and CHD should be estimated by the product of $\beta_{FTO\text{-}Obesity}$ and $\beta_{Obesity\text{-}CHD}$

Mendelian Randomization



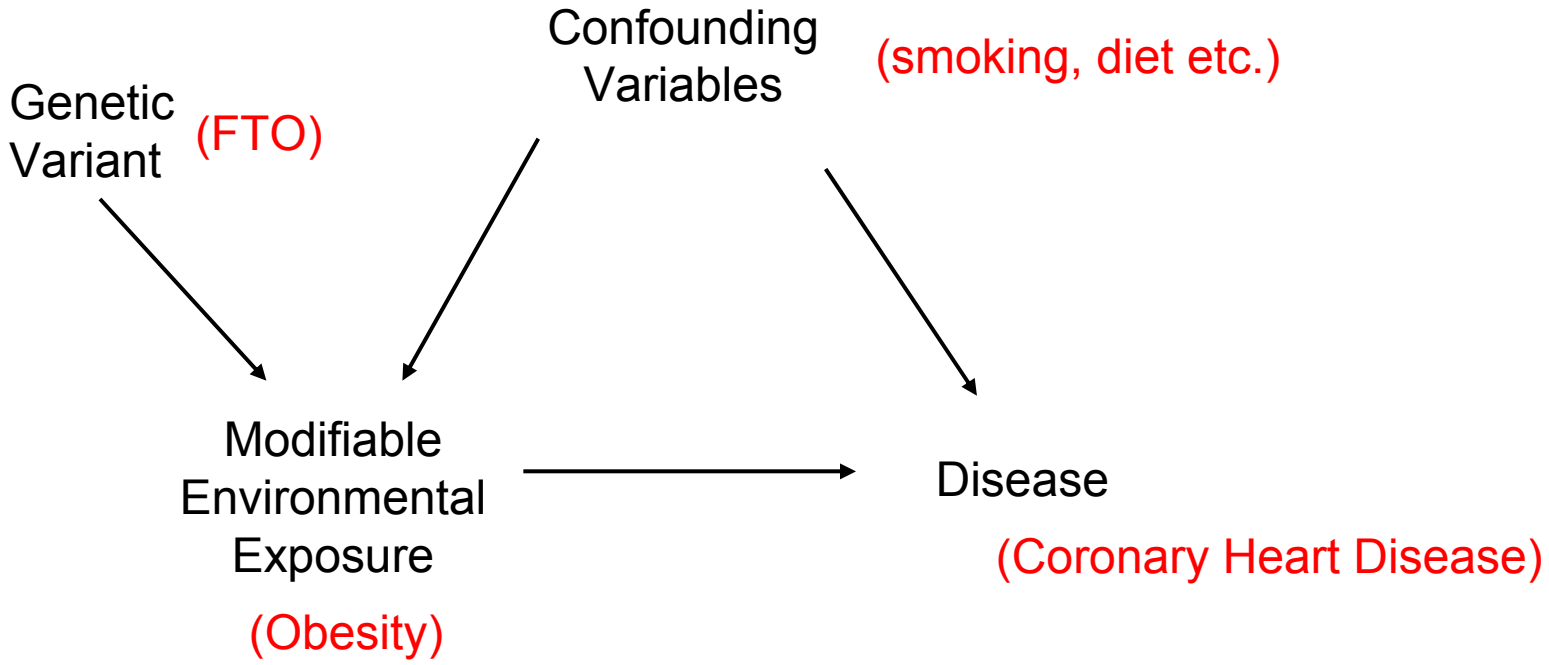
- If CHD causes obesity then $\beta_{FTO\text{-}CHD}$ should be zero.

Mendelian Randomization



- If the relationship between Obesity and CHD is purely correlational (i.e. due to confounding) then $\beta_{FTO\text{-}CHD}$ should be 0

Mendelian Randomization



- Genotype is associated with the environmental exposure of interest
- Genotype is NOT associated with confounders
- Genotype is only related to its outcome via its association with the modifiable environmental exposure

Mendelian Randomization

- Mendelian Randomization is a way of using a genetic variant(s) to make causal inferences about (modifiable) environmental risk factors for disease and health related outcomes

- Environmental exposures (e.g. Obesity) can be modified ! Genetic factors cannot (at least for the moment…)

- Still a relatively new approach that has problems (i.e. finding genetic proxies for environmental exposures- multiple instruments?)

…but a LOT of scope for development…

Could SEM be used to enhance MR?
